(Received for publication January 15, 2004)

Landomycin E (LaE) overproducing strain *Streptomyces globisporus* SMY622 has been developed using UV induced mutagenesis and selection for streptomycin resistance. SMY622 has been shown by HPLC to produce 200-fold higher amounts of LaE when comparing with parental strain. The levels of transcription of regulatory gene \( \text{Indl} \) and oxygenase gene \( \text{IndE} \) are two times higher in the mutant than in the wild type. Gene \( \text{rpsL} \) for ribosomal protein S12 from SMY622 was shown to contain point mutation K43R. Possible reasons for increased LaE synthesis in SMY622 are discussed.

Improvement of production of clinically or industrially valuable antibiotics in bacteria is of great economic importance. The low level production is found in strains producing both natural and so called "hybrid" antibiotics (resulted from heterologous gene expression or gene knockout experiments). Great variety of gene and cellular engineering methods as well as random mutagenesis is used to increase the production of desired compounds.

Landomycins (La) are group of polyketide angucycline antibiotics having interesting spectrum of antitumor activities in vitro. However in vivo studies showed their high cytotoxicity with regard to normal cells. Development of novel La derivatives with increased antitumor activities or decreased side effects has immense theoretical and practical interest.

Two La producers are known-*Streptomyces cyanogenus* S136 (principal product-LaA) and *S. globisporus* 1912 (produces LaE-trisaccharide intermediate to LaA, never found in *S. cyanogenus* culture broths; Fig. 1A). Gene clusters for LaE (\( \text{Ind} \)) and LaA (\( \text{Ian} \)) biosynthesis have been cloned. Genes controlling first steps of LaE polyketide framework synthesis were studied through gene disruption techniques. Wild type *S. globisporus* 1912 produces LaE at very low level, and disruption of cyclase genes involved in LaE synthesis resulted in trace production of respective intermediates. Further, *S. globisporus* strain was constructed impaired in last deoxysugar attachment and C11-hydroxylation. Monoglycosylated La identified are supposed to be attractive targets for "structure-activity relationships" studies. Although they are produced very poorly, that hinders their scrutiny. All these facts have prompted us to develop LaE superproducer that can be used as more convenient host for future experiments on combinatorial biosynthesis of novel La.

We used UV-induced mutagenesis of *S. globisporus* spores to look for streptomycin resistant (Sm\(^+\)) mutants. Obtained Sm\(^+\) mutants were screened for increased LaE production. The selection of the overproducing mutants resistant to aminoglycosides is well established for actinorhodin producers *S. coelicolor* A3(2) and *S. lividans* 30, salinomycin and erythromycin producers *S. albus* and *Saccharopolyspora erythraea*, respectively, and the reasons for increased antibiotic production are thoroughly studied. Here we report the generation of the

strain *S. globisporus* SMY622 producing 200-fold higher quantities of LaE in comparison with parental strain 1912. The results of initial experiments aiming at understanding of the molecular mechanisms of LaE overproduction are presented.

**Materials and Methods**

**Bacterial Strains and Plasmids Used**

These are listed in the Table 1.

**Culture Conditions for *S. globisporus* and *E. coli Strains**

*S. globisporus* strains were grown at 30°C. Oatmeal medium (OM; oatmeal 3%, agar 1.8%, pH 9.0 before auto-claving) was used to obtain *S. globisporus* spores and to plate *E. coli-S. globisporus* matings. For fermentations, *S. globisporus* strains were grown for 3 days in SG medium<sup>9</sup>.

For total and plasmid DNA preparation, EGFP production analysis *S. globisporus* cultures grown in TSB medium<sup>10</sup> were used. *E. coli* strains were grown on LA or LB<sup>11</sup>. Where it was necessary, 100 µg/ml of ampicillin, 50 µg/ml of kanamycin, 25 µg/ml of chloramphenicol and apramycin, various quantitites of streptomycin (Sm) were added to the media.

**Mutation**

Spores from 5 days old *S. globisporus* 1912 culture were suspended in saline and treated with UV rays in dose leading to approx. 1% survival of the spore population. Irradiated spores were spread on OM plates supplemented with 2.5 µg/ml of Sm (Growth of parental strain was inhibited completely at 0.5 µg/ml of Sm). Induced Sm resistant (Sm<sup>R</sup>) mutants that grew on 2.5 µg/ml of Sm were replica plated onto OM plates supplemented with 100, 200, 300, 500, 1000 µg/ml of Sm in order to determine their actual
Sm resistance level.

**Analysis of LaE Production and Resistance to Antibiotics**

Pure sample of LaE was kindly provided by Prof. J. ROHR (College of Pharmacy, Kentucky, USA). TLC and HPLC of La has been done essentially as described. The total protein in the specimens taken from fermentation media was determined by Bradford. The amount of LaE produced by the strains were calculated using standard calibrating HPLC and expressed with regard to the same amount of total protein. The resistance of *S. globisporus* strains to antibiotics was determined via titration of spores on OM plates with various concentrations of antibiotics or with the help of discs with antibiotics (Fereyn, Russia).

**DNA Manipulations**

Genomic DNA from *S. globisporus* strains and plasmid DNA from *E.coli* was isolated using standard protocols. T4-DNA ligase, *Pfu* I and *Taq* thermopolymersases and restriction enzymes were used as recommended by the suppliers. Other DNA manipulations were performed following standard procedures as specified by manufacturers (MBI Fermentas, NEB, Invitrogen, Boehringer Mannheim, Pharmacia). Nucleotide sequences were determined on a Beckman Coulter CEQ2000XL sequencer and analyzed using DNASIS software (version 2.1, Hitachi Software Engineering) and BLAST programs. *E. coli* transformation and intergeneric matings *E. coli-Streptomyces* were performed as described. In case of SMY622 strain mycelia instead of spores were used in the matings.

**Microscopy of *S. globisporus* Strains Exspressing EGFP Gene**

Sample preparation and EGFP production analysis was done as described. Here we used Fluoroview confocal system (Olympus) with an Olympus OL BX50 microscope and 488nm argon laser.

**Cloning of rpsL Gene Internal Fragment from *S. globisporus* 1912 and SMY622**

Primers to conservative regions of *S. lividans* rpsL gene were designed and used in PCR to amplify 0.32kb DNA fragments from both 1912 and SMY622 genomic DNA as templates. SFXhoI (5'-GAAGG GCCGGCAGGACAAGCTCGAGAAG; site for *Xho* I is underlined) is complementary to the region of rpsL starting from 10th amino acid, and SRXbaI (5'-CGGGCTGGTCTCGGTCTAGACAGGCT; site for *Xba* I is underlined)-to the end of rpsL (from115th aa). BioRad thermal cycler iCycler was used at the following conditions: 3 minutes of incubation at 96°C; 30 cycles of 96°C for 1 minute, 65°C for 1 minute, 72°C for 1 minute; and a final step at 72°C for 10 minutes. After finishing lu of *Taq* polymerase was added and mixture was incubated at 72°C for 10 minutes to generate terminal adenine nucleotides for cloning into T-vector. PCR products were purified using GFX Gel Band Purification kit (Amersham Biosciences) and cloned into pT7Blue T-vector. Recombinant plasmids were mapped with *Xho* I and *Xba* I restriction endonucleases. Five independent clones harboring rpsL from each strain were sequenced to minimize the mistakes of PCR and sequencing. Within these two groups of plasmids were selected referred to as pT7rpsL1 (rpsL from wild type 1912) and pT7rpsL2 (from SMY622).

**Results and Discussion**

Wild type strain *S. globisporus* 1912 producer up to 2.8±0.4 mg/liter of LaE under our fermentation conditions. Attempts to develop more optimal fermentation process leading to significant increase in LaE synthesis were unsuccessful. Spontaneous Sm r mutants at appeared at frequency (4.1±0.6)×10⁻⁸, when Sm concentration was 2.5µg/ml, and they did not produce significantly higher amounts of LaE. UV-induced mutagenesis *S. globisporus* 1912 has resulted in appearance of Sm r mutants at frequency (6.0±1.0)×10⁻⁴. In total, 2710 Sm r clones were obtained. Preliminary selection based on degree of LaE accumulation in OM agar (visible as dark blue pigmentation) showed that approx. 6 % (162 clones) possessed higher level of LaE production that parental strain. Analytical TLC showed that among 162 clones, 114 produced LaE roughly 5–10-fold, 45 produced 10–50-fold, 3 produced more than 50-fold. Once clone from the latter group marked as SMY622 was taken for detailed analysis. *S. globisporus* strain showed low frequency spontaneous Sm r mutants appearance, in comparison with what is described about Sm r mutants of *S. coelicolor*, *S. lividans*, *S. albus*, *Saccharopolyspora erythraea*, *S. kanamyceticus*. Thus we looked for LaE overproducers amonug UV induced mutants. This approach proved to have higher efficiency over screening of spontaneous Sm r mutants.

LaE Production and Morphology of SMY622

SMY622 has been shown to produce roughly 200-fold...
quantities of LaE (560 mg/liter) when comparing with parental strain. While wild type produce spores abundantly, SMY622 fails to sporulate on various replete agar media and Hopwood minimal medium. Unlike initial strain, SMY622 mycelium can be easily scraped out from agar plates, and septa of it’s substrate mycelium are shorter than in wild type (as we could judge from confocal microscopy of liquid cultures). Mutations of Sm resistance are shown to have pleiotropic effects on morphology of the mutants of *S. albus, Saccharopolyspora erythraea*[^7], however, the presence of other mutations scattered in SMY622 genome can not be ruled out. We tested the level of SMY622 resistance to Sm and it appeared to be resistant to as much as 1000 µg of Sm per ml of medium. SMY622 has essentially the same as 1912 strain resistance pattern to aminoglycosides (kanamycin, gentamycin), polyketides (erythromycin, oleandomycin, tetracycline), β-lactams (ampicillin, benzylpenicillin, carbenicillin) and rifampicin.

The dramatic increase of LaE production in SMY622 can be partially accounted for very low basal level of LaE synthesis in 1912 strain. Certain mutations within gene *rpsL* for ribosomal protein S12 lead to Sm' phenotype and overproduction of secondary metabolites in *S. lividans* and *S. coelicolor*. These mutations are believed to have global positive effect on ribosome stability, translational accuracy and cellular metabolism[^6]. As evident from HPLC the production of other unrelated with LaE pigments and polyketides is increased in SMY622 (data not shown). This hints at possible analogies in molecular mechanisms mediating LaE and actinorhodin overproduction in respective mutants.

Transcription of LaE Biosynthetic Genes *IndI* and *IndE* in SMY622

The increased LaE production should be rooted in enhanced expression of LaE biosynthetic and, possibly, regulatory genes. To verify this assumption, we tested the expression of EGFP gene from promoter region of LaE pathway specific regulatory gene *IndI*. In the same manner we have checked the expression of oxygenase gene *IndE*, which is localized upstream of the rest structural *Ind* genes (Fig. 1B). Recombinant plasmids pIJ8660H and pIJ8660E[^17].

harboring \textit{Indl} and \textit{IndE} promoters regions fused to EGFP gene, respectively, were transferred into SMY622 and 1912 strains. The measurements of green fluorescence intensities were done each 12 hours of culture growth up to 72 hours. It was found that during first 48 hours of growth the average level of $P_{\text{Indl}}$-EGFP and $P_{\text{IndE}}$-EGFP expression is 2 and 1.5 times higher, respectively, in SMY622 than in 1912 (Fig. 2). We wondered whether it is possible to increase further \textit{Indl} transcription in mutant and wild type strains and thus to enhance LaE production. Additional \textit{Indl} copies on plasmid pSI2-9 have been introduced into SMY622 and 1912. pSI2-9 is $\phi$C31-based integrative plasmid existing in at least three copies per \textit{S. globisporus} genome\textsuperscript{9,13}. LaE production in SMY622 and 1912 increased in 1.3 and 11 times, respectively, after introduction of pSI2-9. Thus, for SMY622, the top level of LaE production so reached was approx. 0.72 g per 1 liter of fermentation medium. In this strain increased \textit{Indl} copy number caused only little enhancement of LaE biosynthesis. Probably, there is some maximal possible level of LaE production for given strain, which can not be improved by simple changes in \textit{Indl} gene dosage. This hints at existence of yet unknown feedback regulatory mechanism linking LaE synthesis and \textit{Ind} genes expression and preventing the cells from overproduction of potentially toxic compound. This mechanism could function through binding of antibiotic with \textit{Indl} promoter or LndI, by analogy to the situation described in doxorubicin biosynthesis\textsuperscript{18}. Summarizing the experimental data presented here, we suggest that increased expression of regulatory gene \textit{Indl} in SMY622 is one of the reasons for it’s LaE overproduction phenotype.

Analysis of \textit{rpsL} Gene from \textit{S. globisporus} SMY622

There is strong evidence that Sm resistance accompanied by enhanced antibiotic production frequently results from

Fig. 2. Average EGFP expression profile from \textit{Indl} (A) and \textit{IndE} (B) promoters in SMY622 (■) and 1912 (♦) measured by confocal microscopy scanning of respective strains cultures in different time-points of growth.
mutations in the rpsL gene for ribosomal protein S12\(^\text{15}\). We therefore sequenced and compared the rpsL genes from wild type and SMY622 mutant. Sequenced fragments showed end-to-end identity with S. lividans and S. coelicolor rpsL genes. SMY622 has been shown to contain single mutation within rpsL gene fragment where the altered nucleotide (from A to G) was found at the position 128. This results in an alteration of Lys-43 to Arg.

K43R mutation was isolated and characterized in S. coelicolor and S. lividans. Although it confers these strains to high level of resistance to Sm (200 µg/ml), it does not appear to activate actinorhodin production in S. lividans TK21 or S. coelicolor\(^\text{15}\). Nevertheless, K43R substitution shows restrictive phenotype (increased transitional accuracy)\(^\text{6}\). Translational machinery has highly conservative nature not only within genus Streptomyces but also between different taxons of higher order. Thus it seems to be unlikely, that K43R mutation would result in phenotype different from that ones described for other studied streptomycetes. We believe that identified mutation contributes at least partially to Sm\(^\text{r}\) phenotype of SMY622, but the reason for LaE overproduction lies outside of rpsL gene.

UV mutagenesis used in our selection scheme, can induce several mutations in SMY622 affecting it’s Sm resistance and cellular metabolism at the levels of transcription and translation. Another evidence for presence of unknown mutations in SMY622 is it’s exceptionally high level of Sm resistance. S. globisporus mutants producing 5–50 fold quantities of LaE were resistant up to 300 µg/ml of Sm, whereas SMY622-to 1 mg/ml. This line of reasoning allows us to suggest tentatively, that SMY622 carries a special set of mutations positively affecting Indl transcription in particular and other yet not examined regulatory mechanisms. In any case, studied LaE overproducer does not possess mutations within rpsL gene, commonly found in actinorhodin overproducing S. coelicolor and S. lividans strains\(^\text{6,7,19}\). This makes interesting further in-depth studying of SMY622 strain as a potential source of discovery of novel useful mutations for improvement of antibiotic production.

In conclusion, the utility of Sm\(^\text{r}\) mutants selection has been demonstrated for LaE overproducers development. Further LaE synthesis improvement can be achieved on combining random Sm\(^\text{r}\) mutants selection and Indl regulatory gene manipulations. Initial investigations addressed the question about mutations nature leading to LaE increased synthesis, which most likely are distinct from that described for S. lividans and S. coelicolor Sm\(^\text{r}\) mutants.
